### Preface

The subject of low-thrust, ion rockets has interested me since I first learned of such vehicles in an undergraduate astrodynamics course. Air Force duties prevented me from keeping abreast of new developments over the past few years, however. I welcomed the opportunity of working on this subject for my thesis.

I would like to acknowledge the help of my advisor, Dr. William Wiesel. But I especially want to thank my wife and typist, Jan, for her understanding and help over the past 18 months. I also hope my two daughters, Laura and Leslie, will forgive me for the lack of attention they have had to experience.

### List of Symbols

a	semi-major axis
$a_f$	final a
$a_i$	initial a
B	second position angle of anti-sun point
D	function of $\lambda_1, \lambda_2, a, f, s$
DU	earth distance unit
e	orbital eccentricity
f	true anomaly
F	integrand of performance index
$F_0$	constant in computation of $C_0$
g	true anomaly at shadow entry
G	universal gravitation constant
$G_0$	constant in computation of $C_0$
H	Hamiltonian
i	orbital inclination
$i_f$	final i
J	performance index
L	first position angle of anti-sun point
m	one-half actual shadow angle
$\dot{m}_p$	specific mass flow rate
$M_\oplus$	mass of earth
n	mean motion
$R_\odot$	angular semi-diameter of sun
s	angle between ascending node and shadow exit
t	time

$T$  total acceleration from thrust  
 $T_0$  initial  $T$   
 $TU$  earth time unit  
 $u$  control variable  
 $U$  radial acceleration component  
 $V$  tangential acceleration component  
 $W$  normal acceleration component  
 $X$   $\partial m / \partial a$   
 $Y$   $\partial m / \partial i$   
 $TP$  orbital period of satellite  
 $\alpha$  thrust angle in orbit plane  
 $\alpha_0$  right ascension of sun  
 $\gamma$  thrust angle out of orbit plane  
 $\delta_0$  declination of sun  
 $\lambda$  Lagrange multiplier  
 $\mu$  gravitational parameter  
 $\pi_s$  parallax of satellite  
 $\pi_0$  parallax of sun  
 $\sigma_0$  one-half maximum shadow angle  
 $T$  independent variable in slow timescale problem  
 $\omega$  argument of perigee  
 $\Omega$  longitude of the ascending node

Abstract

This paper examines the use of discontinuous low thrust for orbital transfers between two non-coplanar, circular orbits. The vehicle is assumed to be a solar-powered, ion rocket that cannot operate when it is within the earth's shadow. Two timescales are used to derive a minimum fuel trajectory. The fast timescale solution maximizes a change in inclination when given a change in semi-major axis for a single orbit. The slow timescale solution combines fast timescale results to obtain the minimum fuel trajectory. Results are presented for three specific transfers requiring varying amounts of shadow penetration. It is shown that the fuel penalty caused by discontinuous thrust is very small. However, there can be a moderate increase in total trip time if the time within shadow is large.

## DISCONTINUOUS LOW THRUST ORBIT TRANSFER

### I Introduction

Electric propulsion research continues to seek new methods of accomplishing future missions in space.<sup>1</sup> Electrically propelled vehicles offer two important advantages for anticipated missions dealing with large space structures. One advantage is an increase in payload ratio which will allow more massive structures to be propelled. The other advantage comes from the extremely low acceleration available from electric thrusters. The large space structures being proposed will be flimsy and unable to withstand large accelerations. Electric propulsion offers a way of moving these large structures around in space.

Although there are many versions of electric thrusters, they all have common characteristics. The most notable are high specific impulse, low mass flow rate and low thrust. These devices provide thrust by electrically accelerating charged ions and then exhausting them into space.

Several authors (Alfano<sup>2</sup>, Moeckel<sup>3</sup>, Ehrike<sup>4</sup>, and Stuhlinger<sup>5</sup>) have shown that the optimal trajectory for orbital transfers using continuous low thrust is an outward spiral. Alfano has derived an optimal control law to perform transfers that include changes in both inclination

and semi-major axis. All these solutions have been based on the use of continuous low thrust.

But continuous thrust may not be available. The electric power used to drive these thrusters will probably be produced by solar cells or a nuclear power plant. Since nuclear power sources weigh more per kilowatt than solar cells and since nuclear power is becoming less attractive in general, it is reasonable to assume that many of these vehicles will be solar-powered.<sup>6</sup> A solar-powered rocket has one serious disadvantage, however. It will not work when it is in the earth's shadow. Therefore, such a craft could not provide continuous thrust.

If tangential thrust were applied only when the vehicle is in sunlight, a circular orbit would not remain circular very long. Since the previous control schemes all assumed circular orbits would remain circular, they are not valid for discontinuous low thrust. This paper addresses the problem of using discontinuous low thrust for non-coplanar transfers between circular orbits.

The derivation is divided into two problems of differing time scales. The fast timescale problem optimizes the changes in orbital elements over one orbit with vehicle mass held constant. The slow timescale problem uses the results of the fast timescale optimization, while updating the mass and acceleration on each orbit.

## II Fast Timescale Problem

The fast timescale problem addresses the changes in orbital elements that occur during one revolution of the central body. The solution should produce a thrust profile which will maximize a change in either inclination or semi-major axis when a particular change in the other is specified. Thrust application is only possible when the solar-powered spacecraft is in sunlight.

### Derivation

The following derivation assumes two-body motion with the earth as the central body. Electric engines produce low thrust and hence cause only small changes in the orbital elements during one orbit. Consequently, general perturbation theory is used in that all the orbit elements are considered constant during each orbit. Also, fuel consumption is low enough that mass is considered constant during one orbit.

The equations of motion are given by Lagrange's planetary equations in their acceleration component form:<sup>7</sup>

$$\frac{d\Omega}{dt} = \frac{w (1-e^2)^{\frac{1}{2}} \sin(f+\omega)}{n a (1 + e \cos f) \sin i} \quad (1)$$

$$\frac{di}{dt} = \frac{w (1-e^2)^{\frac{1}{2}} \cos(f+\omega)}{n a (1 + e \cos f)} \quad (2)$$

$$\frac{d\omega}{dt} = \frac{-U (1-e^2)^{\frac{1}{2}} \cos f}{n a e} + \frac{V (1-e^2)^{\frac{1}{2}} (2 + e \cos f) \sin f}{n a e (1 + e \cos f)} - \frac{W (1-e^2)^{\frac{1}{2}} \sin(f+\omega) \cot i}{n a (1 + e \cos f)} \quad (3)$$

$$\frac{de}{dt} = \frac{U (1-e^2)^{\frac{1}{2}} \sin f}{n a} + \frac{V (1-e^2)^{\frac{1}{2}}}{n a e} \left[ 1 + e \cos f - \frac{1 - e^2}{1 + e \cos f} \right] \quad (4)$$

$$\frac{da}{dt} = \frac{2 U e \sin f}{n (1-e^2)^{\frac{1}{2}}} + \frac{2 V (1 + e \cos f)}{n (1-e^2)^{\frac{1}{2}}} \quad (5)$$

where  $a$  is the semi-major axis;  $e$  is the eccentricity;  $i$  is inclination;  $\omega$  is the argument of perigee;  $\Omega$  is the longitude of the ascending node;  $f$  is the true anomaly;  $U$ ,  $V$  and  $W$  are the radial, tangential and normal acceleration components, respectively; and  $n$  is the mean motion.

$$n = (\mu / a^3)^{\frac{1}{2}} \quad (6)$$

where

$$\mu = G M_{\oplus} \quad (7)$$

and  $G$  is the universal gravitation constant and  $M_{\oplus}$  is the

mass of the earth.

For transfers between circular orbits with continuous low thrust, many authors have shown that the optimum thrust profile requires negligible radial thrust. It has also been shown that the use of purely tangential thrust causes only negligible changes in eccentricity for transfers to geosynchronous altitude when the thrust acceleration is less than  $10^{-3}$  g's.<sup>5</sup> But when thrust is applied over only part of the orbit, eventual changes in eccentricity can be expected. It is also possible that the optimum thrust profile would require that eccentricity be allowed to vary from zero. But the planetary equations can be greatly simplified if the dependence on eccentricity can be eliminated.

To eliminate eccentricity from the planetary equations, an additional constraint is added to the problem. It will be required that the change in eccentricity for each orbit be equal to zero. Since the initial orbit is circular, this constraint forces  $e$  to remain zero for the entire profile. Radial thrust will be used to negate changes in  $e$  that would be caused by pure tangential thrust.

Although this profile may not be the absolute optimum because of the additional constraint, it will be shown that it is at least near optimum.

The requirement that  $e = 0$  causes the planetary equations to become

$$\frac{d\Omega}{dt} = \frac{W \sin(f+\omega)}{n a \sin i} \quad (8)$$

$$\frac{di}{dt} = \frac{W \cos(f+\omega)}{n a} \quad (9)$$

$$\frac{d\omega}{dt} \text{ is undefined for a circular orbit} \quad (10)$$

$$\frac{de}{dt} = \frac{U \sin f}{n a} + \frac{2 V \cos f}{n a} \quad (11)$$

$$\frac{da}{dt} = \frac{2 V}{n} \quad (12)$$

An explanation is in order as to why Eqs (8) and (9) contain  $\omega$ , when the argument of perigee is undefined for circular orbits. In most problems dealing with circular orbits,  $\omega$  is set equal to zero and then dropped from the equations. Implicit in this operation is that  $f$  will be measured from the ascending node, since  $\omega$  in Eqs (8) and (9) represents a phase shift from the ascending node. In the derivation that follows,  $f$  will be measured from the point at which the spacecraft exits the earth's shadow. In this paper, shadow entry and exit points are considered the boundaries of the umbra. To avoid confusion,  $s$  will be used as the phase shift from the ascending node to the

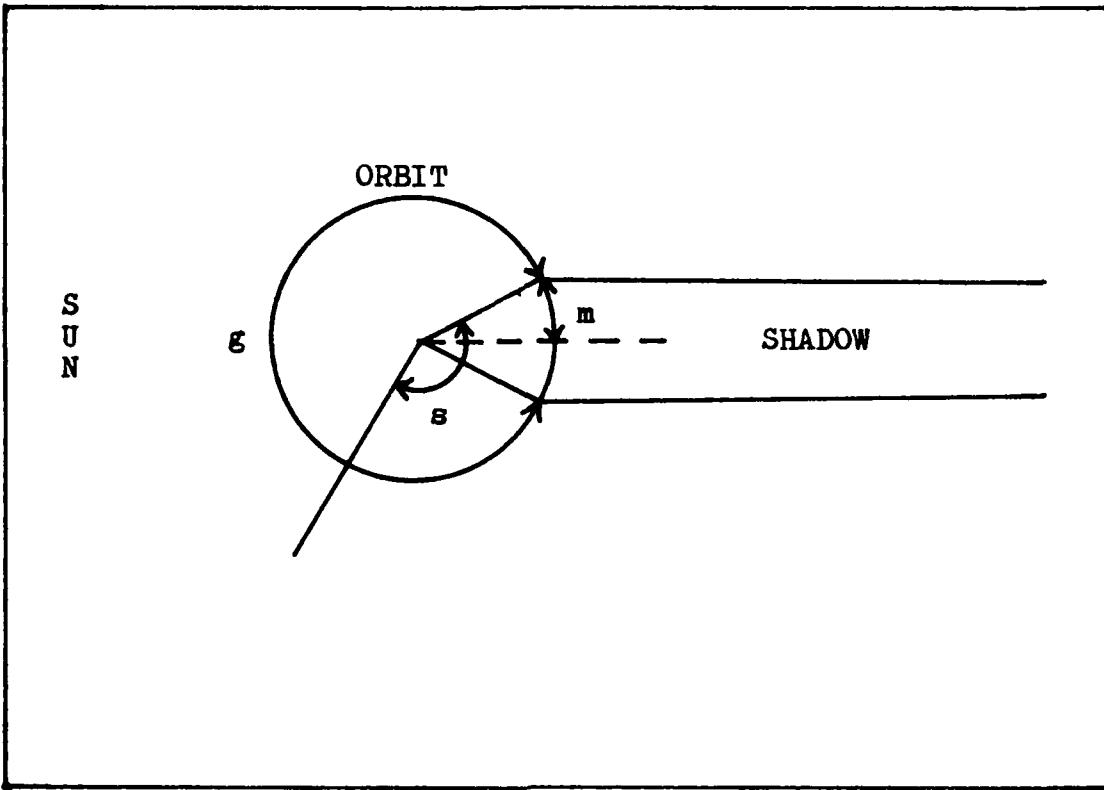

Fig. 1. Shadow Boundaries

shadow exit point. Also,  $g$  will be a measure of the angle from shadow exit to the next shadow entry and  $m$  will be one-half of the angle of shadow. See Figure 1 for a depiction of these angles. Substituting  $s$  for  $\omega$  gives

$$\frac{d\Omega}{dt} = \frac{w \sin(f+s)}{n a \sin i} \quad (13)$$

$$\frac{di}{dt} = \frac{w \cos(f+s)}{n a} \quad (14)$$

Since  $n = df/dt$ , a change of independent variable can be

made from t to f. Substitution yields

$$\frac{d\Omega}{df} = \frac{w \sin(f+s)}{n^2 a \sin i} \quad (15)$$

$$\frac{di}{df} = \frac{w \cos(f+s)}{n^2 a} \quad (16)$$

$$\frac{de}{df} = \frac{U \sin f + 2 V \cos f}{n^2 a} \quad (17)$$

$$\frac{da}{df} = \frac{2 V}{n^2} \quad (18)$$

Substituting Eq (6) gives

$$\frac{d\Omega}{df} = \frac{w a^2 \sin(f+s)}{\mu \sin i} \quad (19)$$

$$\frac{di}{df} = \frac{w a^2 \cos(f+s)}{\mu} \quad (20)$$

$$\frac{de}{df} = \frac{a^2}{\mu} (U \sin f + 2 V \cos f) \quad (21)$$

$$\frac{da}{df} = \frac{a^3 2 V}{\mu} \quad (22)$$

To determine the changes in the orbital parameters for one orbit, these equations should be integrated from 0 to  $2\pi$ . But  $U$ ,  $V$ , and  $W$  are zero when the spacecraft is in shadow; so these equations can be integrated from 0 to  $g$  where  $g$  is the true anomaly at the point where the shadow is entered. The changes in orbital elements are then

$$\Delta\Omega = \int_0^g \frac{W a^2 \sin(f+s) df}{\mu \sin i} \quad (23)$$

$$\Delta i = \int_0^g \frac{W a^2 \cos(f+s) df}{\mu} \quad (24)$$

$$\Delta e = \int_0^g \frac{a^2}{\mu} (U \sin f + 2V \cos f) df \quad (25)$$

$$\Delta a = \int_0^g \frac{2V a^3 df}{\mu} \quad (26)$$

The thrust accelerations  $U$ ,  $V$  and  $W$  can be modeled as functions of  $f$ . From Figure 2,

$$U = T \cos\gamma \cos\alpha \quad (27)$$

$$V = T \cos\gamma \sin\alpha \quad (28)$$

$$W = T \sin\gamma \quad (29)$$

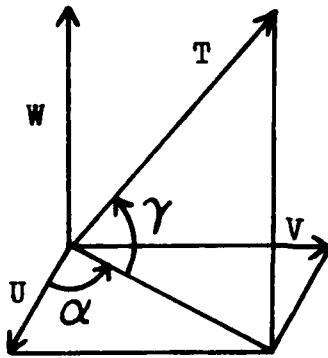

Fig 2. Acceleration Components

where

$$\gamma = \gamma(f) \quad (30)$$

$$\alpha = \alpha(f) \quad (31)$$

Substitution yields

$$\Delta \Omega = \frac{T a^2}{\mu \sin i} \int_0^g \sin \gamma \sin(f+s) df \quad (32)$$

$$\Delta i = \frac{T a^2}{\mu} \int_0^g \sin \gamma \cos(f+s) df \quad (33)$$

$$\Delta e = \frac{T a^2}{\mu} \int_0^g (\cos \gamma \cos \alpha' \sin f + 2 \cos \gamma \sin \alpha' \cos f) df \quad (34)$$

$$\Delta a = \frac{2 T a^3}{\mu} \int_0^g \cos \gamma \sin \alpha' df \quad (35)$$

To find the optimum thrust history for one orbit, the approach used is to maximize  $\Delta i$  for a given  $\Delta a$ , subject to the additional constraint that  $\Delta e = 0$ . The performance index with constraint relationships is

$$J(\alpha, \gamma) = \int_0^g \frac{T a^2}{\mu} \sin \gamma \cos(f+s) df$$

$$+ \lambda_1 \left[ \int_0^g \frac{2 T a^3}{\mu} \cos \gamma \sin \alpha' df - \Delta a \right]$$

$$+ \lambda_2 \int_0^g \frac{T a^2}{\mu} (\cos \gamma \cos \alpha' \sin f + 2 \cos \gamma \sin \alpha' \cos f) df \quad (36)$$

where  $\lambda_1$  and  $\lambda_2$  are Lagrange multipliers. Simplifying,

$$J(\alpha, \gamma) = \int_0^T \frac{a^2}{\mu} \left[ \sin \gamma \cos(f+s) + \lambda_1 a^2 \cos \gamma \sin \alpha \right. \\ \left. + \lambda_2 (\cos \gamma \cos \alpha \sin f + 2 \cos \gamma \sin \alpha \cos f) \right] df \\ - \lambda_1 \Delta a \quad (37)$$

Call the integrand  $F$  for convenience. The calculus of variations can be used to show that the above functional has a stationary value when the following Euler equations are satisfied.<sup>8</sup>

$$\frac{\partial F}{\partial \alpha} - \frac{d}{df} \left[ \frac{\partial F}{\partial \alpha'} \right] = 0 \quad (38)$$

$$\frac{\partial F}{\partial \gamma} - \frac{d}{df} \left[ \frac{\partial F}{\partial \gamma'} \right] = 0 \quad (39)$$

where primes indicate the derivative with respect to the independent variable,  $f$ . Since  $\alpha'$  and  $\gamma'$  do not occur in  $F$ , The Euler equations become algebraic equations rather than differential equations. Therefore,  $J$  has an extremal when

$$\frac{\partial F}{\partial \alpha} = 0 \quad (40)$$

and

$$\frac{\partial F}{\partial \gamma} = 0 \quad (41)$$

After performing the differentiation,

$$\frac{\partial F}{\partial \alpha} = \frac{\lambda_1^2 T a^3}{\mu} \cos \gamma \cos \alpha + \frac{\lambda_2^2 T a^2}{\mu} (2 \cos \gamma \cos \alpha \cos f - \cos \gamma \sin \alpha \sin f) \quad (42)$$

$$\frac{\partial F}{\partial \gamma} = \frac{T a^2}{\mu} \cos \gamma \cos(f+s) - \frac{\lambda_1^2 T a^3}{\mu} \sin \gamma \sin \alpha - \frac{\lambda_2^2 T a^2}{\mu} (\sin \gamma \cos \alpha \sin f + 2 \sin \gamma \sin \alpha \cos f) \quad (43)$$

Substituting Eqs (42) and (43) into Eqs (40) and (41) and then simplifying gives

$$\tan \alpha = \frac{2(\lambda_1 a + \lambda_2 \cos f)}{\lambda_2 \sin f} \quad (44)$$

$$\tan \gamma = \frac{\cos(f+s)}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2]^{\frac{1}{2}}} \quad (45)$$

Therefore, the optimal control law becomes

$$\alpha = \tan^{-1} \left[ \frac{2(\lambda_1 a + \lambda_2 \cos f)}{\lambda_2 \sin f} \right] \quad (46)$$

$$\gamma = \tan^{-1} \left[ \frac{\cos(f+s)}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2]^{1/2}} \right] \quad (47)$$

Substitution of Eqs (46) and (47) into Eqs (32) through (35) gives

$$\Delta \Omega = \frac{T a^2}{\mu \sin i} \int_0^s \frac{g \sin(f+s) \cos(f+s) df}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2 + \cos^2(f+s)]^{1/2}} \quad (48)$$

$$\Delta i = \frac{T a^2}{\mu} \int_0^s \frac{g \cos^2(f+s) df}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2 + \cos^2(f+s)]^{1/2}} \quad (49)$$

$$\Delta e = \frac{T a^2}{\mu} \int_0^s \frac{g [\lambda_2 \sin^2 f + 4 \cos f (\lambda_1 a + \lambda_2 \cos f)] df}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2 + \cos^2(f+s)]^{1/2}} \quad (50)$$

$$\Delta a = \frac{4 T a^3}{\mu} \int_0^s \frac{(\lambda_1 a + \lambda_2 \cos f) df}{[\lambda_2^2 \sin^2 f + 4(\lambda_1 a + \lambda_2 \cos f)^2 + \cos^2(f+s)]^{1/2}} \quad (51)$$

The two constraint relationships,  $\Delta e = 0$  and  $\Delta a$  as given, can be used to solve for the two Lagrange multipliers,  $\lambda_1$  and  $\lambda_2$ . But these equations must be solved numerically. Before they can be solved numerically, however,  $s$  must be determined.

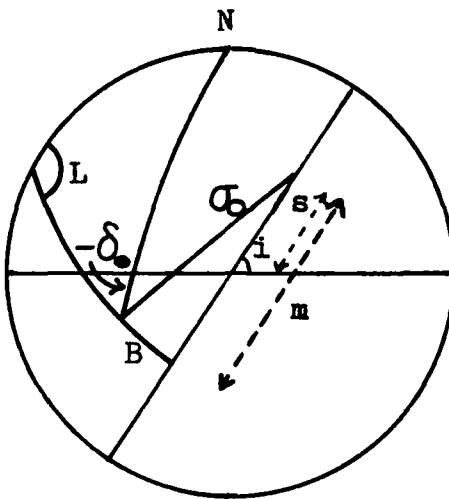

Fig 3. Sun-Orbit Geometrical Relationship

As mentioned earlier,  $s$  is a phase angle measured in the orbit plane between the ascending node and the point where the spacecraft exits the earth's shadow. Link<sup>9</sup> has derived the following expressions for the orbital coordinates of the anti-sun point to the orbital plane.

$$\sin B = -\sin \delta_{\odot} \cos i + \cos \delta_{\odot} \sin i \sin(\alpha_{\odot} - \Omega) \quad (52)$$

$$\sin L = -\cos(\alpha_{\odot} - \Omega) \frac{\cos \delta_{\odot}}{\cos B} \quad (53)$$

where  $B$  and  $L$  are angles as shown in Fig 3,  $\alpha_{\odot}$  and  $\delta_{\odot}$  are the right ascension and declination of the sun. The same reference also gives an expression for half the shadow

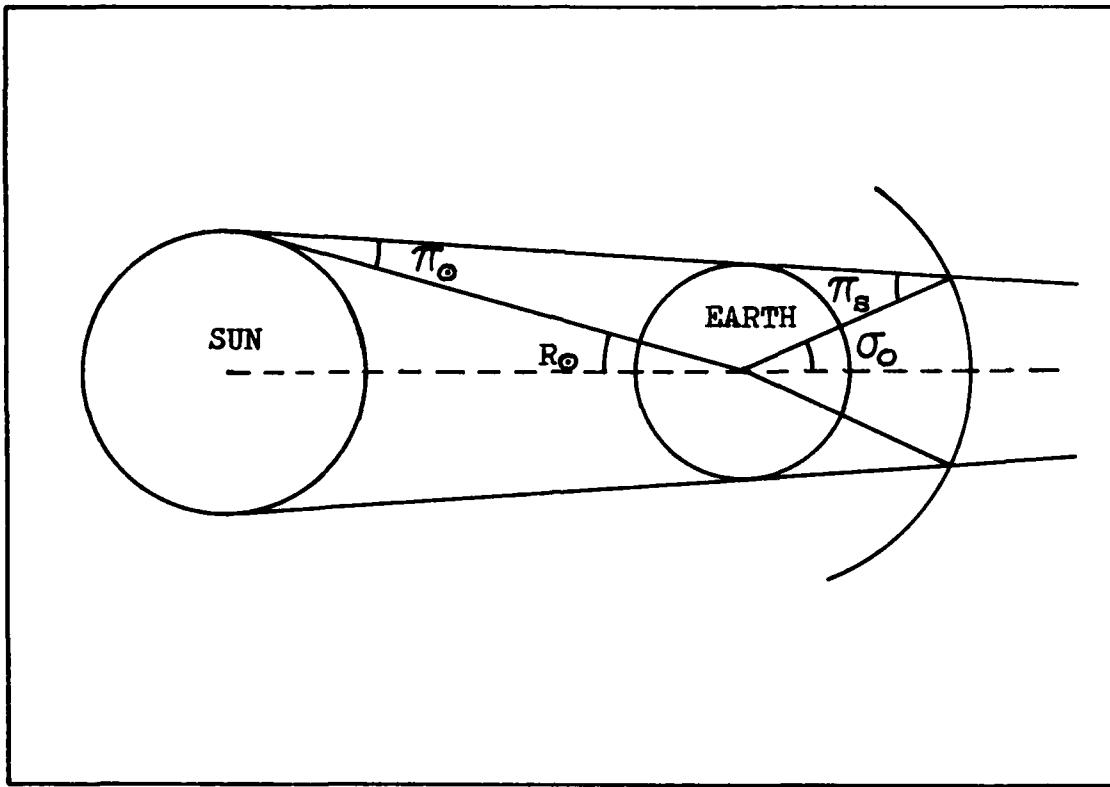

Fig 4. Shadow Geometry

angle,  $m$ :

$$\cos m = \frac{\cos \sigma_o}{\cos B} \quad (54)$$

where  $\sigma_o$  is half of the maximum shadow possible for a given altitude.

$$\sigma_o = \pi_o + \pi_s - R_o \quad (55)$$

where  $\pi_o$  and  $\pi_s$  are the parallaxes of the sun and satellite respectively and  $R$  is the angular semi-diameter of the sun. See Figure 4. It can be seen in Figure 3 that

$$S = \frac{\pi}{2} - L + m \quad (56)$$

When making the preceding calculation, care must be exercised in choosing the proper quadrant for  $L$ . Once  $s$  is known, the upper limit of integration,  $g$ , can be found:

$$g = 2\pi - 2m = 2(\pi - m) \quad (57)$$

But first, for convenience, define

$$u = \lambda_1 a \quad (58)$$

and

$$D = \lambda_2^2 \sin^2 f + 4(u + \lambda_2 \cos f)^2 + \cos^2(f+s) \quad (59)$$

Now the optimum control history for a single orbit can be found in the following manner. Given the orbital elements and the sun-earth geometrical relationship,  $s$  and  $g$  can be computed from Eqs (56) and (57). Then the two constraint relationships,

$$\int_0^g \frac{\lambda_2 \sin^2 f + 4 \cos f (u + \lambda_2 \cos f) \, df}{D^{\frac{1}{2}}} = 0 \quad (60)$$

and

$$\int_0^g \frac{2(u + \lambda_2 \cos f) \, df}{D^{\frac{1}{2}}} = \frac{\Delta a \mu}{2 T a^3} \quad (61)$$

can be solved numerically to determine  $u$  and  $\lambda_2$ . These two values can then be substituted into the control law

which is repeated here;

$$\alpha = \tan^{-1} \left[ \frac{2(u + \lambda_2 \cos f)}{\lambda_2 \sin f} \right] \quad (46)$$

$$\gamma = \tan^{-1} \left[ \frac{\cos(f+s)}{[\lambda_2^2 \sin^2 f + 4(u + \lambda_2 \cos f)^2]^{1/2}} \right] \quad (47)$$

to find the control profile. This profile will maximize  $\Delta i$  for a given  $\Delta a$ , subject to  $\Delta e = 0$ .

### Examples

Several examples are presented here to show the effects caused by various amounts of shadow and varying values of  $u$ . In all the examples, sun-earth relative geometry is assumed such that

$$s = \frac{3\pi}{2} + m \quad (62)$$

This value of  $s$  corresponds to the following conditions:

$$\begin{array}{ll} a = 1.03 \text{ DU} & \alpha_e = 270^\circ \\ \Omega = 180^\circ & \delta_e = -23.47^\circ \end{array}$$

These conditions would exist if the spacecraft were established in a 200 km parking orbit on the first day of winter.

Figure 5 shows the effect of shadow width on  $\lambda_2$ . Notice that when there is no shadow ( $m = 0$ ), then  $\lambda_2 = 0$ . When  $\lambda_2 = 0$ , the constraint equation,  $\Delta e = 0$ , is not necessary.

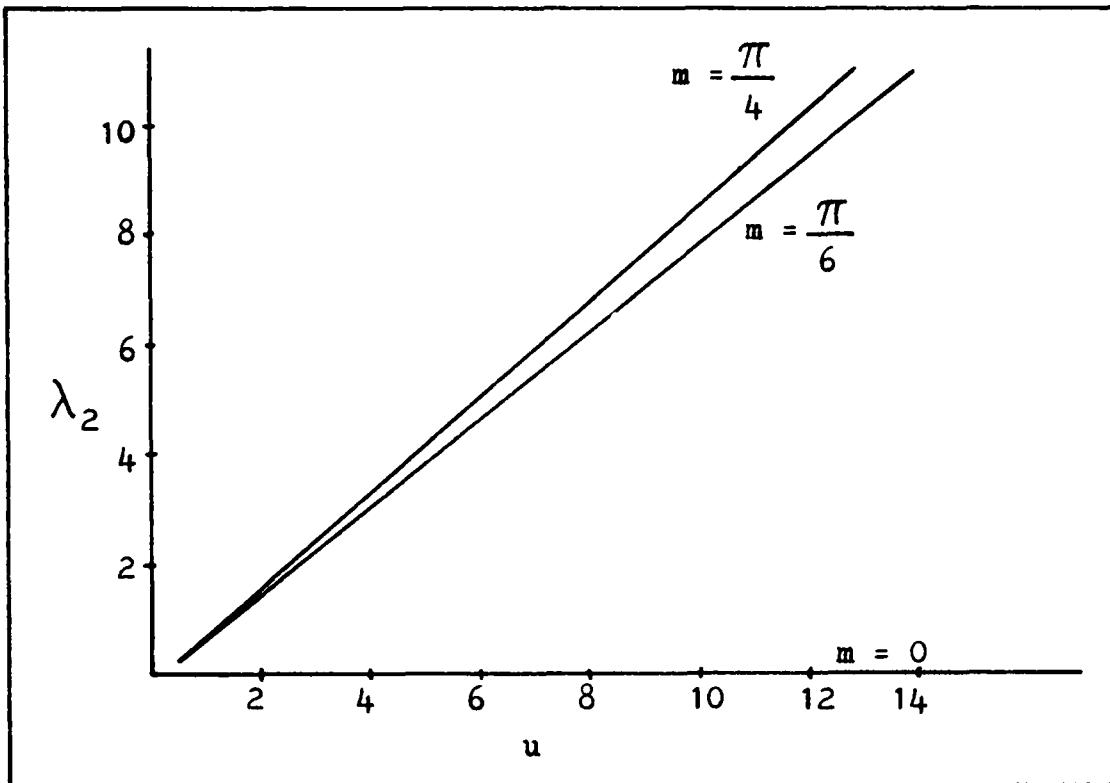

Fig 5. Shadow Effects on  $\lambda_2$

Figure 6 shows the effect of shadow width on  $\Delta a$  and  $\Delta i$ . As would be expected, decreasing shadow width is accompanied by increasing  $\Delta a$  and  $\Delta i$  as a result of longer thrust application. Notice that  $u = 0$  corresponds to inclination change only and that  $u = \infty$  corresponds to semi-major axis change only. For computational purposes,  $u = 100$  can be used for  $u = \infty$ , with good numerical accuracy. A plot of  $\Delta \Omega$  versus  $u$  is not shown since  $\Delta \Omega$  was very near zero for all cases that were examined. Also, since  $\Delta \Omega$  was always at least three orders of magnitude less than  $\Delta a$  and  $\Delta i$ , its equation will be neglected in the remaining derivation.

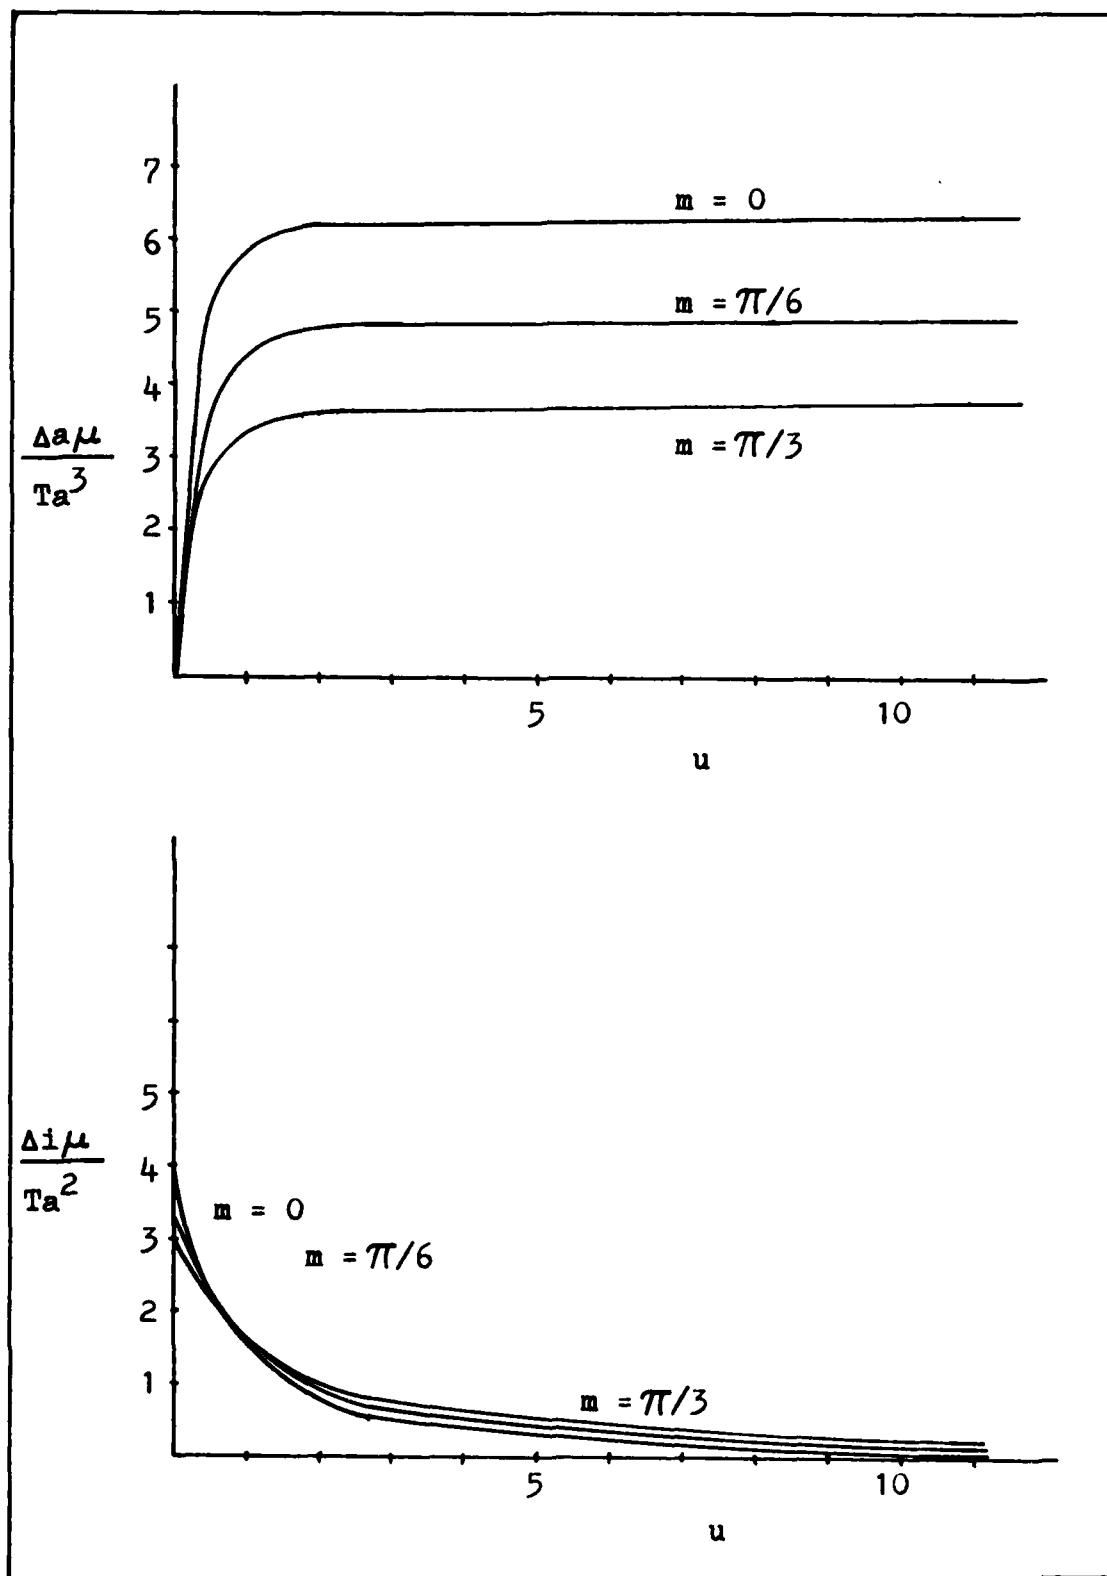

Fig 6. Shadow Effects on  $\Delta a$  and  $\Delta i$

A comparison of the no shadow case and Alfano's results will help verify the derivation in this paper. As mentioned previously, when  $m = 0$ , then  $\lambda_2 = 0$ . For  $\lambda_2 = 0$ ,  $\alpha = \pi/2$  and  $\gamma = \tan^{-1} [\cos(f+s)/2u]$ . These values correspond exactly with those presented in Alfano's paper. Additionally, consider using the control to cause semi-major axis change only. This case corresponds to  $u = \infty$ . By taking the limit as  $u \rightarrow \infty$ , it can be shown that  $\Delta a \mu / T a^3 = 2\pi$ . Finally, when only change in inclination is desired,  $\Delta i \mu / T a^2 = 4$ . Both of the last two results also agree exactly with those presented in Alfano's paper. Therefore, the control law is validated for the special case of no shadow.

Figures 7 through 9 show the effect of the control,  $u$ , for different values of  $m$ , the half-shadow angle. The  $\gamma$  curves appear as would be expected; for  $u = 0$ , all thrust is directed normal for the orbit plane; for greater values of  $u$ , less thrust is directed in the normal direction. The  $\alpha$  curves may appear contradictory at first. As  $u$  increases, one would expect more thrust to be directed tangentially to achieve a greater  $\Delta a$ . But the figures indicate that greater values of  $u$  demand even greater divergence from pure tangential thrust ( $\alpha = \pi/2$ ). Recall, however, that  $\alpha$  only determines the direction of the thrust component in the orbit plane.

The magnitude of that component is  $T \cos \gamma$ . As  $u$

increases,  $\cos\gamma$  increases. So even though it appears that the tangential component decreases due to  $\alpha$ , the coupling through the  $\gamma$  dependence insures that the tangential force is increasing. Of course, the increasing tangential acceleration requires more radial accelerations to maintain  $\Delta\theta = 0$ ; thus causing it to appear that less tangential force is being applied.

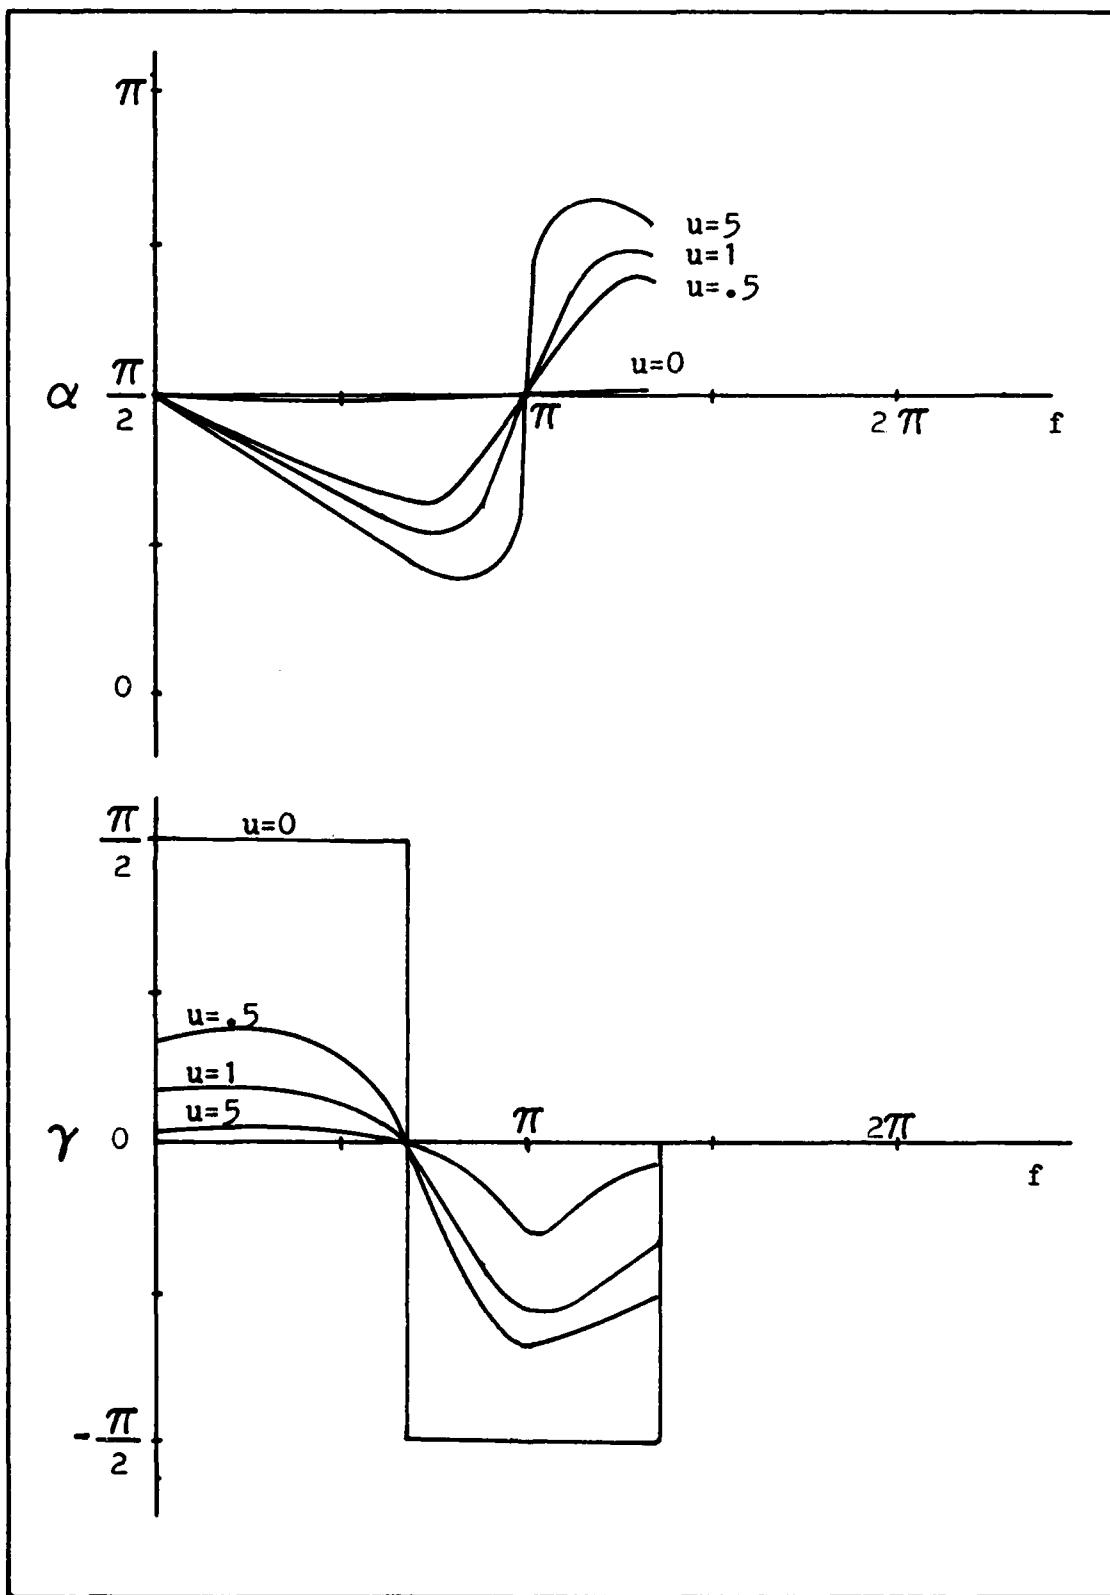

Fig 9.  $\alpha$  and  $\gamma$  for  $m = \pi/3$

### III Slow Timescale Problem

#### Problem Statement

The purpose of solving the slow timescale problem is to determine how much to change semi-major axis and inclination on each orbit so that final boundary conditions are reached in minimum time. Fast timescale results are used to ensure optimal control during each orbit and to define the amount of change possible on a given orbit. Mass is recomputed for each orbit to compensate for propellant loss.

#### Derivation

Before the minimum time control problem can be solved, a few preliminary steps will be taken. An expression is needed for  $da/dt$  and  $di/dt$  for the slow timescale problem. Since the orbital elements change so little on each orbit, these rates can be approximated by

$$\frac{da}{dt} \approx \frac{\Delta a}{\Delta t} \quad (63)$$

$$\frac{di}{dt} \approx \frac{\Delta i}{\Delta t} \quad (64)$$

where  $\Delta t$  is the elapsed time for the particular orbit. For a circular orbit,

$$\Delta t = \frac{2\pi}{\mu} a^{\frac{3}{2}} \quad (65)$$

But the presence of shadow makes the above approximations

inaccurate. The elements  $a$  and  $i$  will only change when the spacecraft is in sunlight. Therefore,  $\Delta t$  must be adjusted to only cover that portion of the orbit when thrust is being applied.

$$\Delta t = \frac{g}{2\pi} T P = 2(\pi - m) \left[ \frac{a^3}{\mu} \right]^{\frac{1}{2}} \quad (66)$$

Substitution yields

$$\frac{da}{dt} = \frac{2 T a^{3/2}}{\mu^{\frac{1}{2}}(\pi - m)} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{\frac{1}{2}}} \quad (67)$$

$$\frac{di}{dt} = \frac{T a^{\frac{1}{2}}}{2\mu^{\frac{1}{2}}(\pi - m)} \int_0^g \frac{\cos^2(f+s) df}{D^{\frac{1}{2}}} \quad (68)$$

Since the problem is to find a minimum thrusting time and hence minimum fuel, successive orbits will combine as if there were no coasting time through the shadow. The coasting time will be computed so the total transfer elapsed time will be known at the end.

As mentioned previously, corrections will be made for each orbit to compensate for increased acceleration caused by decreasing mass. For a constant thrust ion rocket, propellant flow is constant. Acceleration as a function of time can be modeled as

$$T(t) = \frac{T_0}{1 - \frac{\dot{m}}{m_p} t} \quad (69)$$

where  $T_0$  is the initial vehicle acceleration,  $t$  is the time and  $\dot{m}_p$  is the specific mass flow rate (mass flow rate divided by initial vehicle mass).

Since Eqs (67) and (68) can be solved more easily if there is no time dependence, a change of variable can be made. A new independent variable  $\mathcal{T}$  can be defined such that

$$d\mathcal{T} = \left[ \frac{T_0}{1 - \dot{m}_p t} \right] dt \quad (70)$$

Integrating, with  $\mathcal{T} = 0$  when  $t = 0$  yields

$$\mathcal{T} = -\frac{T}{\dot{m}_p} \ln (1 - \dot{m}_p t) \quad (71)$$

$\mathcal{T}$  is the total accumulated velocity change. Minimizing  $\mathcal{T}$  will minimize thrusting time and fuel expended.

Converting from  $t$  to  $\mathcal{T}$  gives

$$\frac{da}{d\mathcal{T}} = \frac{2 a^{3/2}}{\mu^{1/2} (\pi - m)} \int_0^s \frac{(u + \lambda_2 \cos f) df}{D^{1/2}} \quad (72)$$

$$\frac{di}{d\mathcal{T}} = \frac{a^{1/2}}{\mu^{1/2} 2(\pi - m)} \int_0^s \frac{\cos^2(f+s)}{D^{1/2}} \quad (73)$$

Bryson and Ho<sup>10</sup> have shown that a minimum time solution satisfies the following conditions:

$$H(t_f) = 0 \quad (74)$$

$$\frac{\partial H}{\partial u_k} = 0 \quad k = 1, 2, 3, \dots, r \quad (75)$$

$$\lambda_j = -\frac{\partial H}{\partial x_j} \quad j = 1, 2, 3, \dots, q \quad (76)$$

where  $H$  is the Hamiltonian,  $\lambda_j$ 's are Lagrange multipliers,  $x_j$ 's are the state variables, and the  $u_k$ 's are the control variables. In this problem,  $r = 1$  producing only one optimality condition and  $q = 2$  because the simplified system has only two degrees of freedom. These equations will now be applied to this specific problem.

For this problem, the Hamiltonian is

$$H = \lambda_a \frac{da}{dT} + \lambda_i \frac{di}{dT} + 1 \quad (77)$$

Since  $t$  does not appear explicitly in  $H$ ,

$$\dot{H} = 0 \quad (78)$$

Therefore,  $H(t_f) = 0$  implies

$$H(t) = 0 \quad (79)$$

for all  $t \geq 0$ . So

$$\lambda_a \frac{da}{dT} + \lambda_i \frac{di}{dT} + 1 = 0 \quad (80)$$

for all time. Substitution produces

$$\begin{aligned}
 & \lambda_a \left[ \frac{2 a^{3/2}}{\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{\frac{1}{2}}} \right] \\
 & + \lambda_i \left[ \frac{a^{\frac{1}{2}}}{2\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{\cos^2(f+s) df}{D^{\frac{1}{2}}} \right] + 1 = 0
 \end{aligned} \tag{81}$$

In this problem, Eq (75) becomes

$$\lambda_a \frac{\partial}{\partial u} \left[ \frac{da}{dT} \right] + \lambda_i \frac{\partial}{\partial u} \left[ \frac{di}{dT} \right] = 0 \tag{82}$$

But

$$\frac{\partial}{\partial u} \frac{da}{dT} = \frac{2 a^{3/2}}{\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{[\lambda_2^2 \sin^2 f + \cos^2(f+s)] df}{D^{3/2}} \tag{83}$$

and

$$\frac{\partial}{\partial u} \frac{da}{dT} = \frac{-2 a^{\frac{1}{2}}}{\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) \cos^2(f+s) df}{D^{3/2}} \tag{84}$$

Therefore,

$$\lambda_a \left[ \frac{2 a^{3/2}}{\mu^{1/2}(\pi - m)} \int_0^g \frac{[\lambda_2^2 \sin^2 f + \cos^2(f+s)]}{D^{3/2}} df \right] - \lambda_i \left[ \frac{2 a^{1/2}}{\mu^{1/2}(\pi - m)} \int_0^g \frac{(u + \lambda_2 \cos f) \cos^2(f+s)}{D^{3/2}} df \right] = 0 \quad (85)$$

For this problem, after the change of independent variable, Eq (76) becomes

$$\lambda'_a = - \frac{\partial H}{\partial a} \quad (86)$$

$$\lambda'_i = - \frac{\partial H}{\partial i} \quad (87)$$

where the prime indicates differentiation with respect to  $T$ . Now

$$\frac{\partial H}{\partial a} = \lambda_a \frac{\partial}{\partial a} \left[ \frac{da}{dT} \right] + \lambda_i \frac{\partial}{\partial a} \left[ \frac{di}{dT} \right] \quad (88)$$

But, remembering that  $s$  is a function of  $m$  and  $m$  is a function of both  $a$  and  $i$ ,

$$\frac{\partial}{\partial a} \frac{da}{dT} = \left[ \frac{\partial}{\partial a} \frac{da}{dT} \right] + \left[ \frac{\partial}{\partial m} \frac{da}{dT} \right] \frac{\partial m}{\partial a} \quad (89)$$

$$\frac{\partial}{\partial a} \frac{da}{dT} = \frac{3 a^{\frac{1}{2}}}{\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{\frac{1}{2}}} \quad (90)$$

Since  $g$  is also a function of  $m$

$$\begin{aligned} \frac{\partial}{\partial m} \frac{da}{dT} &= \int_0^g \frac{\partial}{\partial m} \frac{2 a^{3/2} (u + \lambda_2 \cos f) df}{\mu^{\frac{1}{2}}(\pi-m) D^{\frac{1}{2}}} \\ &+ \frac{2 a^{3/2} (u + \lambda_2 \cos f)}{\mu^{\frac{1}{2}}(\pi-m) D^{\frac{1}{2}}} \bigg|_g \frac{\partial g}{\partial m} \end{aligned} \quad (91)$$

And, finally

$$\begin{aligned} \frac{\partial}{\partial m} \frac{da}{dT} &= \frac{2 a^{3/2}}{\mu^{\frac{1}{2}}(\pi-m)^2} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{\frac{1}{2}}} \\ &+ \frac{2 a^{3/2}}{\mu^{\frac{1}{2}}(\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) \sin(f+s) \cos(f+s) df}{D^{3/2}} \\ &- \frac{4 a^{3/2} (u + \lambda_2 \cos 2m)}{\mu^{\frac{1}{2}}(\pi-m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{\frac{1}{2}}} \end{aligned} \quad (92)$$

Now, to find  $\partial m / \partial a$ , recall Eqs (52), (54), and (55).

Substitution of the appropriate physical constraints gives

$$\cos \sigma_0 = \left[ 1 - \frac{1}{a^2} \right]^{\frac{1}{2}} F_0 + \frac{1}{a} G_0 \quad (93)$$

where  $F_0$  and  $G_0$  are constants depending on the size of the earth and sun and the distance between them.

$$F_0 = .99994668$$

$$G_0 = .0046229536$$

Also,

$$\cos B = [1 - (\cos \delta_0 \sin i \sin(\alpha_0 - \Omega) - \sin \delta_0 \cos i)^2]^{1/2} \quad (94)$$

$$\frac{\partial m}{\partial a} = \frac{\partial}{\partial a} \left[ \cos^{-1} \left( \frac{\cos \sigma}{\cos B} \right) \right] \quad (95)$$

$$\frac{\partial m}{\partial a} = \frac{G_0 - \frac{F_0}{[a^2 - 1]^{1/2}}}{a^2 [\cos^2 B - \cos^2 \sigma_0]^{1/2}} \quad (96)$$

For convenience, let

$$X = \frac{\partial m}{\partial a} = \frac{G_0 - F_0(a^2 - 1)^{-1/2}}{a^2 [\cos^2 B - \cos^2 \sigma]^{1/2}} \quad (97)$$

Continuing to construct more terms of Eq (88),

$$\frac{\partial}{\partial a} \left[ \frac{di}{dT} \right] = \left[ \frac{\partial}{\partial a} \frac{di}{dT} \right] + \left[ \frac{\partial}{\partial m} \frac{di}{dT} \right] \frac{\partial m}{\partial a} \quad (98)$$

$$\frac{\partial}{\partial a} \frac{di}{dT} = \frac{1}{4\mu^{\frac{1}{2}} a^{\frac{1}{2}} (\pi - m)} \int_0^g \frac{\cos^2(f+s) df}{D^{\frac{1}{2}}} \quad (99)$$

$$\begin{aligned} \frac{\partial}{\partial m} \frac{di}{dT} &= \frac{-a^{\frac{1}{2}}}{\mu^{\frac{1}{2}} (\pi - m)} \int_0^g \frac{\sin(f+s) \cos(f+s) df}{D^{\frac{1}{2}}} \\ &+ \frac{a^{\frac{1}{2}}}{2\mu^{\frac{1}{2}} (\pi - m)^2} \int_0^g \frac{\cos^2(f+s) df}{D^{\frac{1}{2}}} \\ &+ \frac{a^{\frac{1}{2}}}{2\mu^{\frac{1}{2}} (\pi - m)} \int_0^g \frac{\sin(f+s) \cos^3(f+s) df}{D^{3/2}} \\ &- \frac{a^{\frac{1}{2}} \cos^2(s-2m)}{\mu^{\frac{1}{2}} (\pi - m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{\frac{1}{2}}} \end{aligned} \quad (100)$$

Substituting Eqs (90), (92), (97), (99) and (100) into Eq (86) yields

$$\begin{aligned}
 \lambda'_a &= -\lambda_a \left[ \frac{a^{\frac{1}{2}} [3(\pi-m) + 2 \times a]}{\mu^{\frac{1}{2}} (\pi-m)^2} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{\frac{1}{2}}} \right. \\
 &\quad + \frac{2 \times a^{3/2}}{\mu^{\frac{1}{2}} (\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) \sin(f+s) \cos(f+s) df}{D^{3/2}} \\
 &\quad \left. - \frac{4 \times a^{3/2} (u + \lambda_2 \cos 2m)}{\mu^{\frac{1}{2}} (\pi-m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{\frac{1}{2}}} \right] \\
 &\quad - \lambda_i \left[ \frac{(\pi-m) + 2 \times a}{4\mu^{\frac{1}{2}} a^{\frac{1}{2}} (\pi-m)^2} \int_0^g \frac{\cos^2(f+s) df}{D^{\frac{1}{2}}} \right. \\
 &\quad - \frac{x a^{\frac{1}{2}}}{\mu^{\frac{1}{2}} (\pi-m)} \int_0^g \frac{\sin(f+s) \cos(f+s) df}{D^{\frac{1}{2}}} \\
 &\quad \left. + \frac{x a^{\frac{1}{2}}}{\mu^{\frac{1}{2}} (\pi-m)} \int_0^g \frac{\sin(f+s) \cos(f+s) df}{D^{3/2}} \right. \\
 &\quad \left. - \frac{x a^{\frac{1}{2}} \cos^2(s-2m)}{\mu^{\frac{1}{2}} (\pi-m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{\frac{1}{2}}} \right]
 \end{aligned}$$

(101)

In a similar manner,  $\lambda'_i$  can be found to be

$$\begin{aligned}
 \lambda'_i = & -\lambda_a \left[ \frac{2 Y a^{3/2}}{\mu^{1/2}(\pi-m)^2} \int_0^g \frac{(u + \lambda_2 \cos f) df}{D^{1/2}} \right. \\
 & + \frac{2 Y a^{3/2}}{\mu^{1/2}(\pi-m)} \int_0^g \frac{(u + \lambda_2 \cos f) \sin(f+s) \cos(f+s) df}{D^{3/2}} \\
 & \left. - \frac{4 Y a^{3/2} (u + \lambda_2 \cos 2m)}{\mu^{1/2}(\pi-m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{1/2}} \right] \\
 & - i \left[ \frac{-Y a^{1/2}}{\mu^{1/2}(\pi-m)} \int_0^b \frac{\sin(f+s) \cos(f+s) df}{D^{1/2}} \right. \\
 & + \frac{Y a^{1/2}}{2 \mu^{1/2}(\pi-m)^2} \int_0^g \frac{\cos^2(f+s) df}{D^{1/2}} \\
 & + \frac{Y a^{1/2}}{2 \mu^{1/2}(\pi-m)} \int_0^g \frac{\sin(f+s) \cos^3(f+s) df}{D^{3/2}} \\
 & \left. - \frac{Y a^{1/2} \cos^2(s-2m)}{\mu^{1/2}(\pi-m) [\lambda_2^2 \sin^2 2m + 4(u + \lambda_2 \cos 2m)^2 + \cos^2(s-2m)]^{1/2}} \right] \quad (102)
 \end{aligned}$$

where

$$Y = \frac{\partial m}{\partial i} = \frac{-\cos \sigma_0 \sin B \cos(\delta_0 - i)}{\cos^2 B [\cos^2 B - \cos^2 \sigma_0]^{1/2}} \quad (103)$$

Now, Eqs (81) and (85) can be solved simultaneously for  $\lambda_a$  and  $\lambda_i$  in terms of integrals containing the state and control variables. From Eq (85),

$$\lambda_i = \frac{\lambda_a a \int_0^g \frac{[\lambda_2^2 \sin^2 f + \cos^2(f+s)]}{D^{3/2}} df}{\int_0^g \frac{(u + \lambda_2 \cos f) \cos^2(f+s)}{D^{3/2}} df} \quad (104)$$

Substituting this result into Eq (81) gives

$$a = \left[ \frac{1}{Q(u, s)} \right] \frac{2 \mu^{\frac{1}{2}} (\pi - m)}{a^{3/2}} \int_0^g \frac{(u + \lambda_2 \cos f) \cos^2(f+s)}{D^{3/2}} df \quad (105)$$

where

$$Q(u, s) = \int_0^g \frac{4(u + \lambda_2 \cos f)}{D^{\frac{1}{2}}} df \int_0^g \frac{(u + \lambda_2 \cos f) \cos^2(f+s)}{D^{3/2}} df + \int_0^g \frac{\cos^2(f+s)}{D^{\frac{1}{2}}} df \int_0^g \frac{[\lambda_2^2 \sin^2 f + \cos^2(f+s)]}{D^{3/2}} df \quad (106)$$

These two equations can be substituted into either equation (101) or (102) to also produce an integral equation in terms of the state and control variables. Now, using the new expression for Eqs (101) or (102), and the two state Eqs (72) and (73), the minimum time problem can be solved.

There are three equations and three unknowns:  $a$ ,  $i$ , and  $u$ . Solving these equations is not a trivial task, however. Implementation of this solution is described in the following section.

### Implementation

The minimum time profile is determined in the following manner. Choose Eq (101) or (102) to use. To demonstrate, use Eq (101). Pick a starting value for  $\lambda_a$ . Given this  $\lambda_a(0)$ , Eq (105) can be solved numerically to determine what  $u$  would produce that  $\lambda_a$ . Remember that selecting or finding  $u$  also determines  $\lambda_2$  as a result of satisfying the constraint  $\Delta e = 0$ . Now these values of  $u$  and  $\lambda_2$  are used in the state Eqs (72) and (73) to find  $\Delta a$  and  $\Delta i$ . Also,  $a$ ,  $i$  and  $m$  are used to compute  $\Delta t$  and  $\Delta T$ . This  $\Delta T$  is used to find the new  $\lambda_a$ .  $\lambda_a$  is then used to repeat the process until final boundary conditions are met. If final boundary conditions are not met, a new  $\lambda_a(0)$  is chosen. This process continues until a  $\lambda_a(0)$  is found which causes the final boundary conditions to be achieved. Then  $u$  will be determined for the entire profile.

Although this method of solution may sound rather straight forward, there can be some major problems. At first glance, it would appear that one should choose the  $\lambda_i$  equation to use. That equation has fewer terms and  $Y$  as a factor in all its terms. Recall that  $Y$  is the partial of  $m$  with respect to  $i$ . When  $m = 0$ ,  $Y = 0$  and

$$\lambda'_i = 0 \quad (107)$$

Therefore

$$\lambda_i = \text{constant} \quad (108)$$

It was found by experience, however, that in the range of interest for values of  $\lambda_i$ ,  $u$  is double-valued. It was also found that  $\lambda_i$  varied dramatically for different values of  $a$  and  $i$ . See figures 10 and 11. Figure 10 shows  $\lambda_a$  and  $\lambda_i$  versus  $u$  for  $a = 1.03$  DU's and  $i = .4974$  radians. Figure 11 shows the same functions for  $a = 6.6$  DU's (geo-synchronous) and  $i = 0$ . Notice that the  $\lambda_a$  curve maintains its shape and only changes slightly. The  $\lambda_i$  curve, however, is not as well behaved. The peak on that curve shifts upward and to the right. Using  $\lambda_i$ , the optimal profile attempts to move from the right side of the peak to the left. Numerical search schemes in the vicinity of the zero slope diverged and therefore an optimal profile could not be found.

By using the  $\lambda_a$  equation, an optimal profile could be found as long as large values of  $u$  are not encountered. This would occur if the starting  $\lambda_a$  was chosen where the  $\lambda_a$  curve was nearly horizontal. Fortunately, that region corresponds to transfers which will be shown to not be optimal.

The second major problem in implementing this solution is developing a search scheme to find the correct

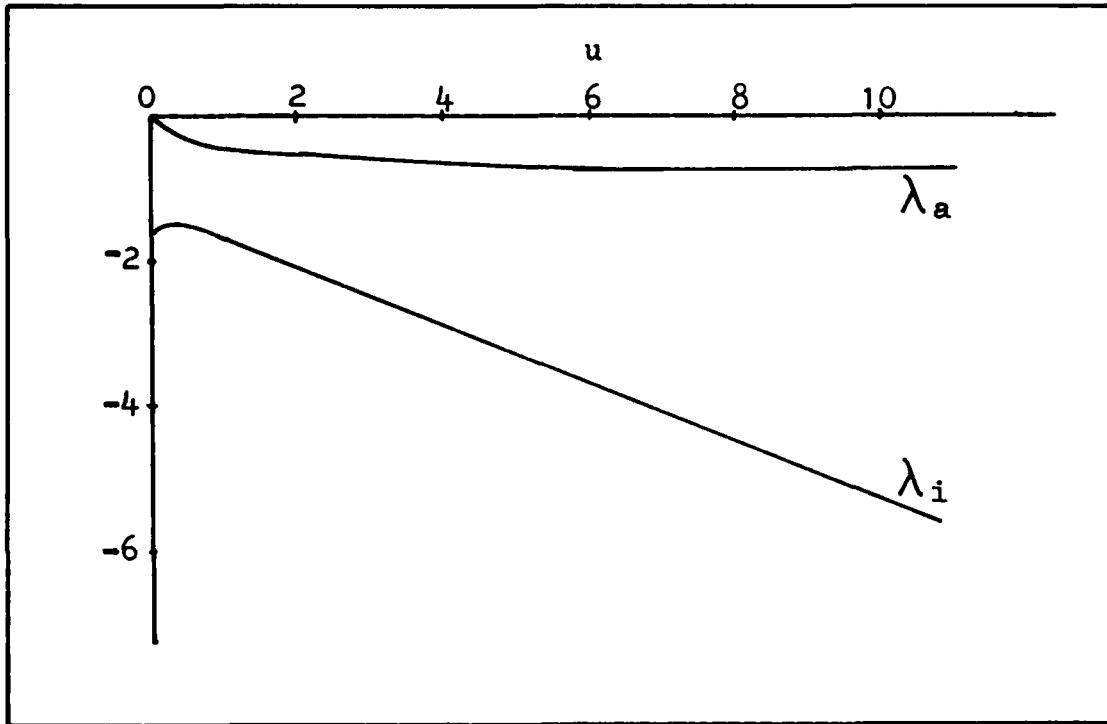

Fig 10.  $\lambda_a$  and  $\lambda_i$  for Initial Conditions

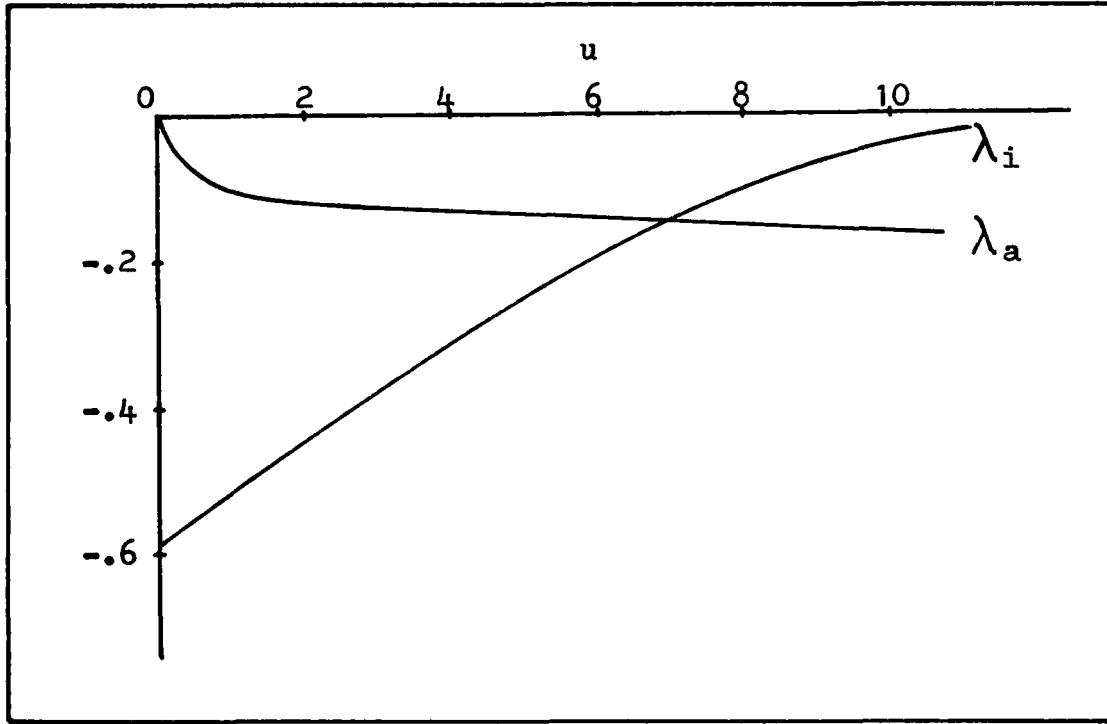

Fig 11.  $\lambda_a$  and  $\lambda_i$  for Final Conditions

$\lambda_a(0)$ . For all cases considered in this paper, choosing a  $\lambda_a(0)$  near zero caused  $a_f$  to be reached before  $a_f$ . For  $\lambda_a(0)$  in the horizontal portion of its graph,  $a_f$  was reached first. The optimum choice of  $\lambda_a(0)$  for a minimum time solution occurs somewhere between these other values. Unfortunately, more than one local minimum may exist in this region. In the next chapter, it will be shown that this does not appear to be a serious problem for the particular transfers that were considered. When more than one minimum occurred, the transfer times were very close to one another.

In summary, the method outlined in the chapter can be used to solve the minimum time transfer problem. The solution may only be a local minimum, however.

#### IV Results

The equations derived in the preceeding chapters were applied to three specific transfers. One transfer did not involve any time in shadow; another caused the spacecraft to be in shadow for about half its orbits; and the last transfer required shadow penetration during about 95% of its orbits. All three transfers required the same semi-major axis and inclination change. For all,  $a_i$  corresponded to a parking orbit altitude of 200 km and  $a_f$  corresponded to geo-synchronous altitude. Beginning and ending inclinations were chosen to cause the varying amounts of shadow time. In all three cases,

$$\alpha_0 = 270^\circ$$

$$\Omega = 180^\circ$$

$$\delta_0 = -23.47^\circ$$

Also, to aid comparison, Alfano's values for specific impulse (5000 sec) and specific mass flow rate ( $2.0 \times 10^{-7}$ /sec) were used. Figures 12 through 14 show how  $a$ ,  $i$  and shadow angle vary during each of the three profiles.

#### Case I

This case was the transfer that did not penetrate the earth's shadow at any time. This case was designed primarily to validate the slow timescale solution by comparing it with Alfano's results for the identical transfer. Using the solution presented here, the total accumulated velocity change ( $T$ ) was only 2.7% greater than Alfano's. The difference was caused primarily by numerical problems associated with finding  $\lambda_2$  from the constraint relationship,  $\Delta e = 0$ .

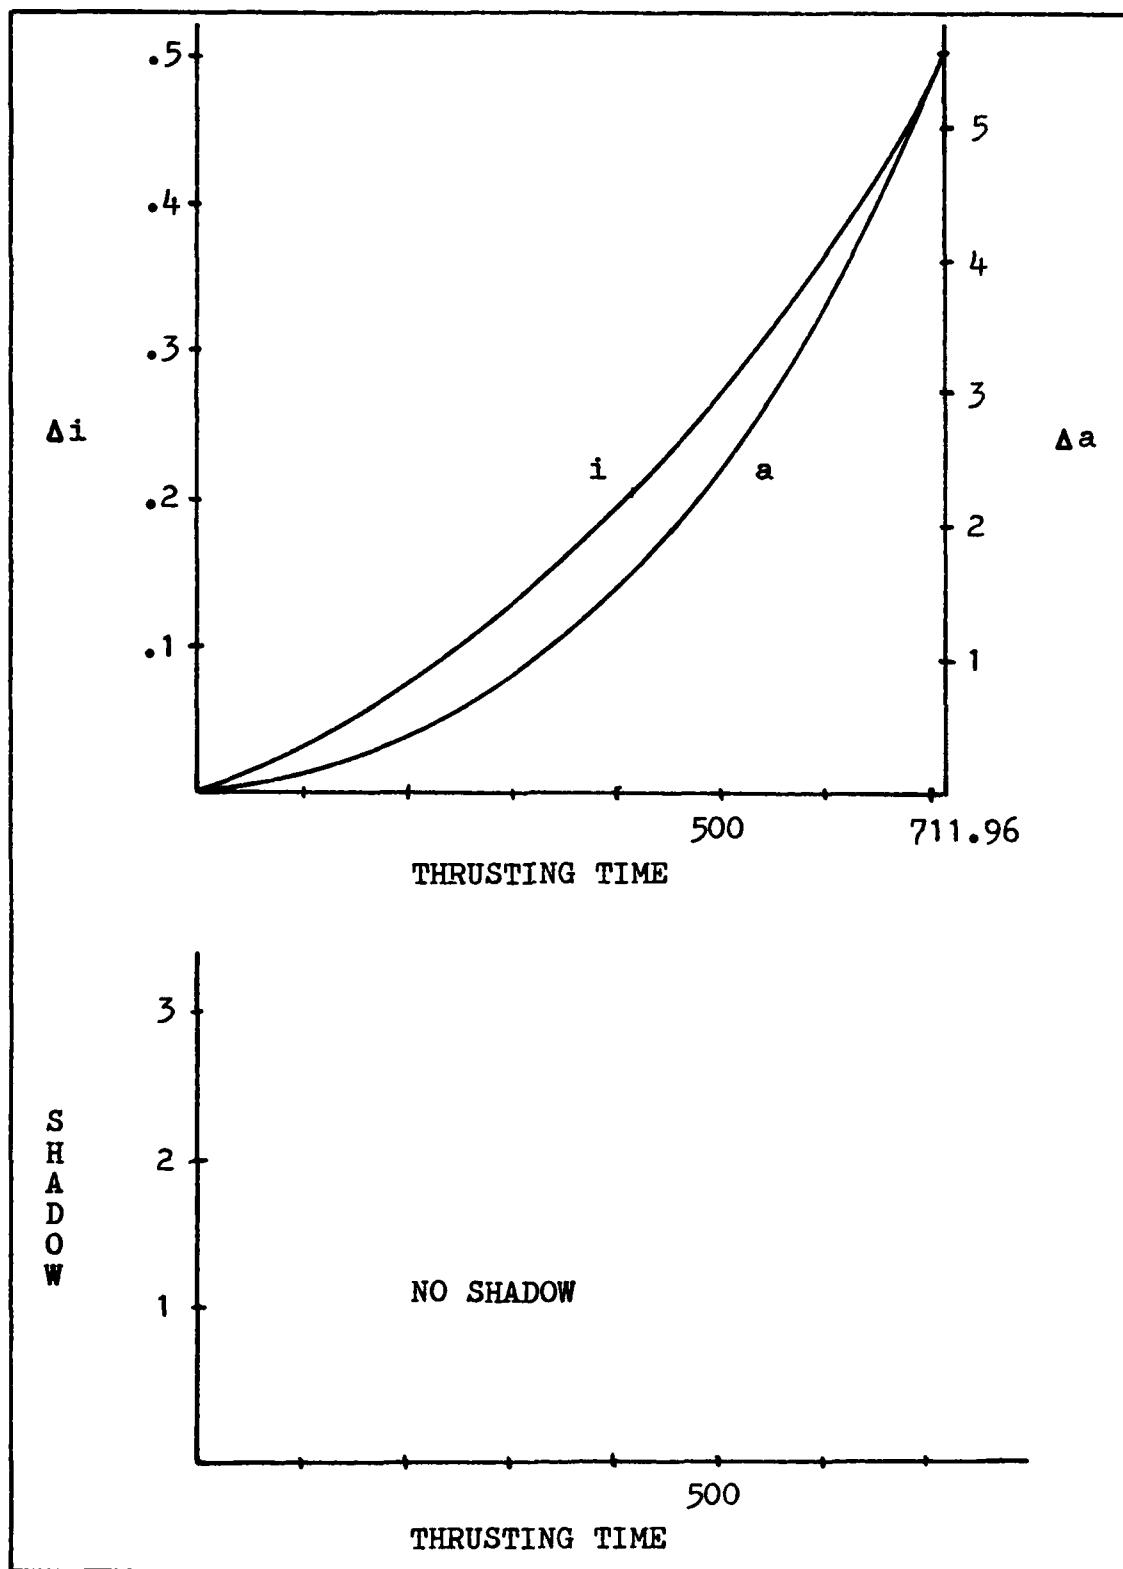

Fig 12. CASE I

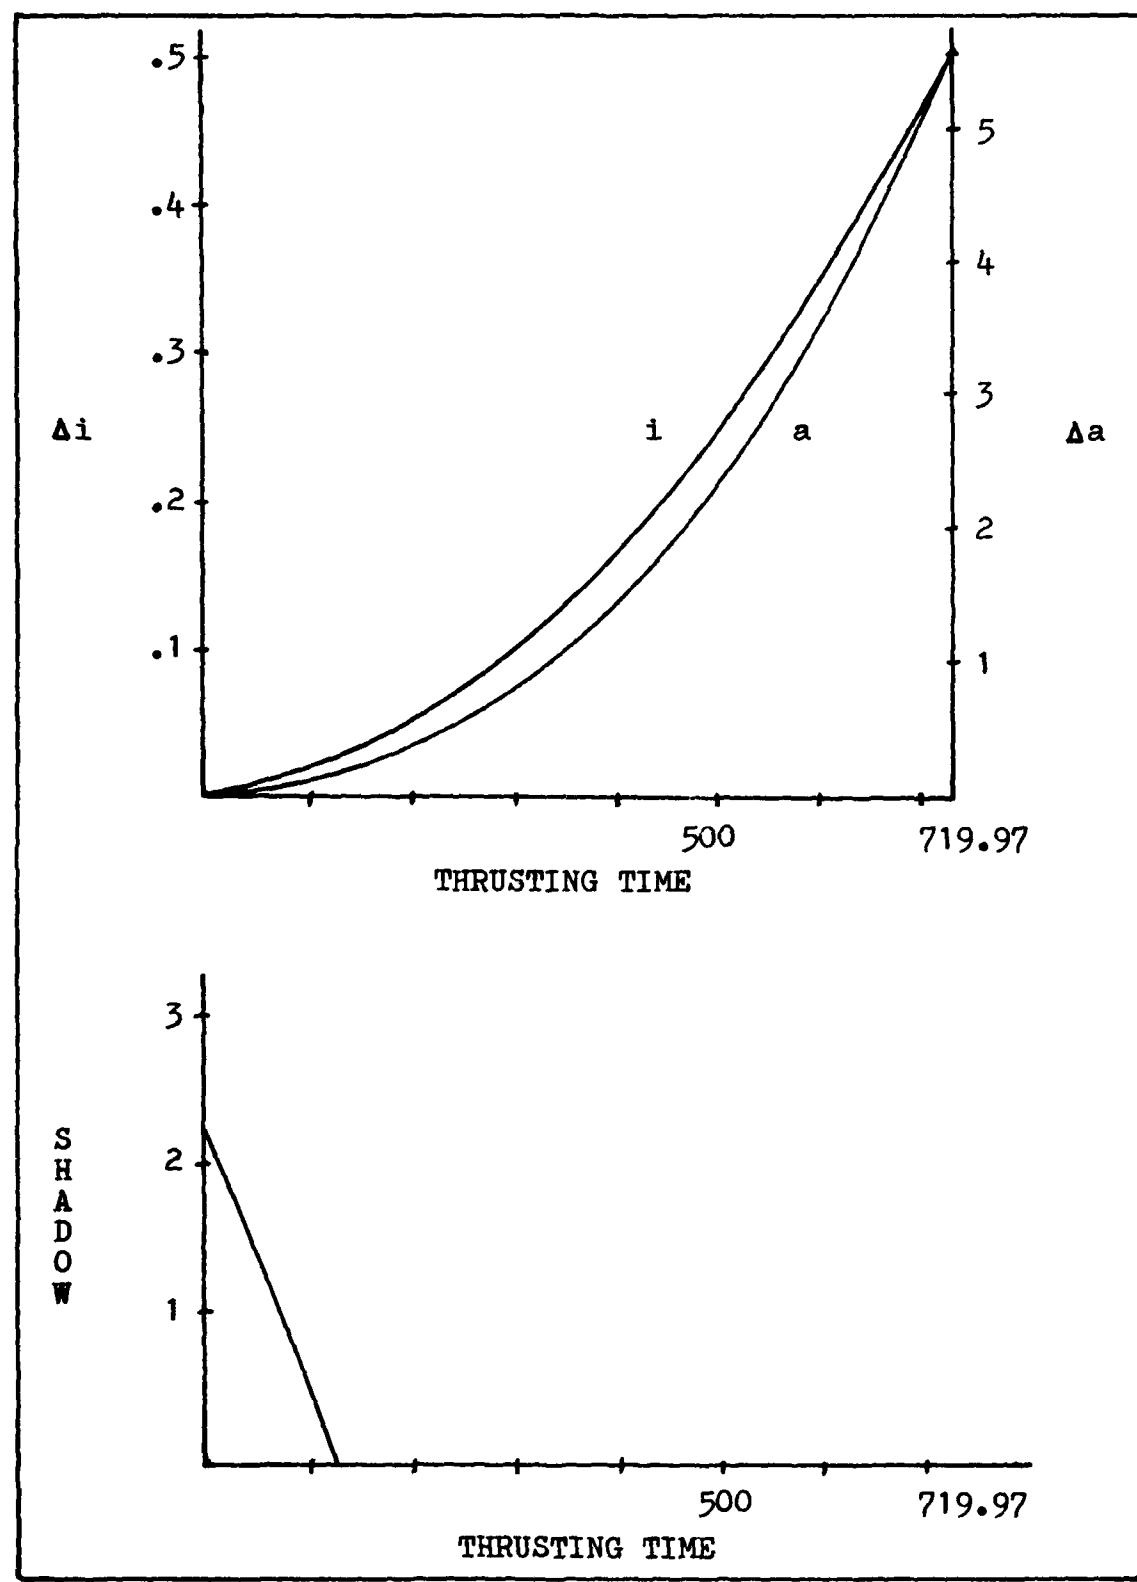

Fig 13. CASE II

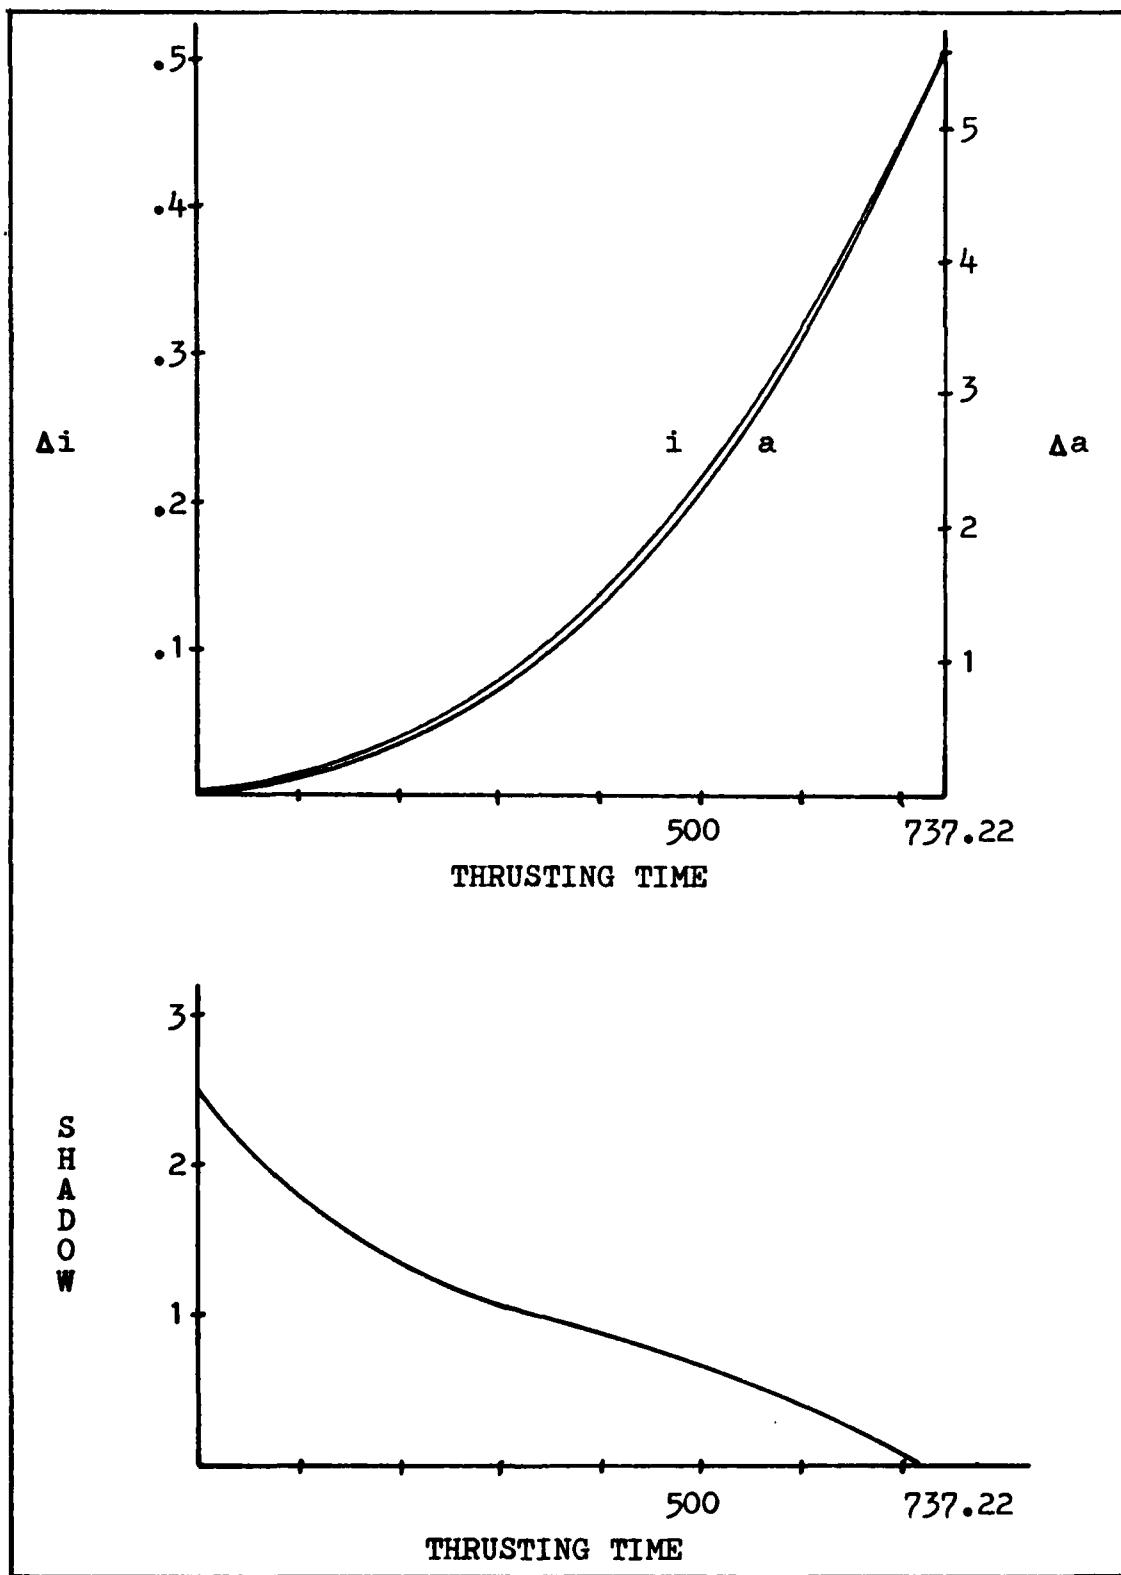

Fig 14. CASE III

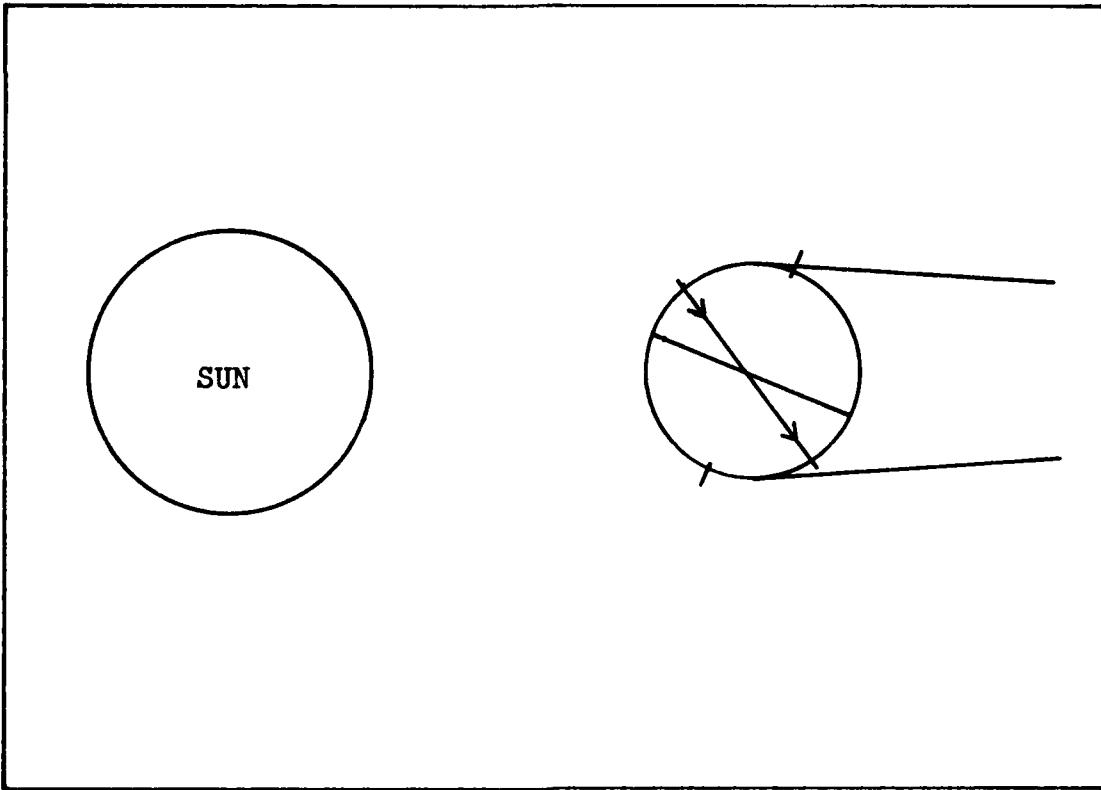

Fig 15. Case II Initial Conditions

Although  $\lambda_2$  should equal zero when there is no shadow,  $\lambda_2$  was always found to be very near zero. Consequently, a small amount of radial thrust was applied throughout the transfer making it less efficient. A more accurate search routine for  $\lambda_2$  should reduce or eliminate the difference. For this reason, it is believed that this solution is validated.

#### Case II

The geometry for this case is shown in Figure 15. The initial conditions would occur with a noon launch out of Cape Canaveral on the first day of winter. In this transfer, the spacecraft experiences an eclipse on each of its first 20 orbits.

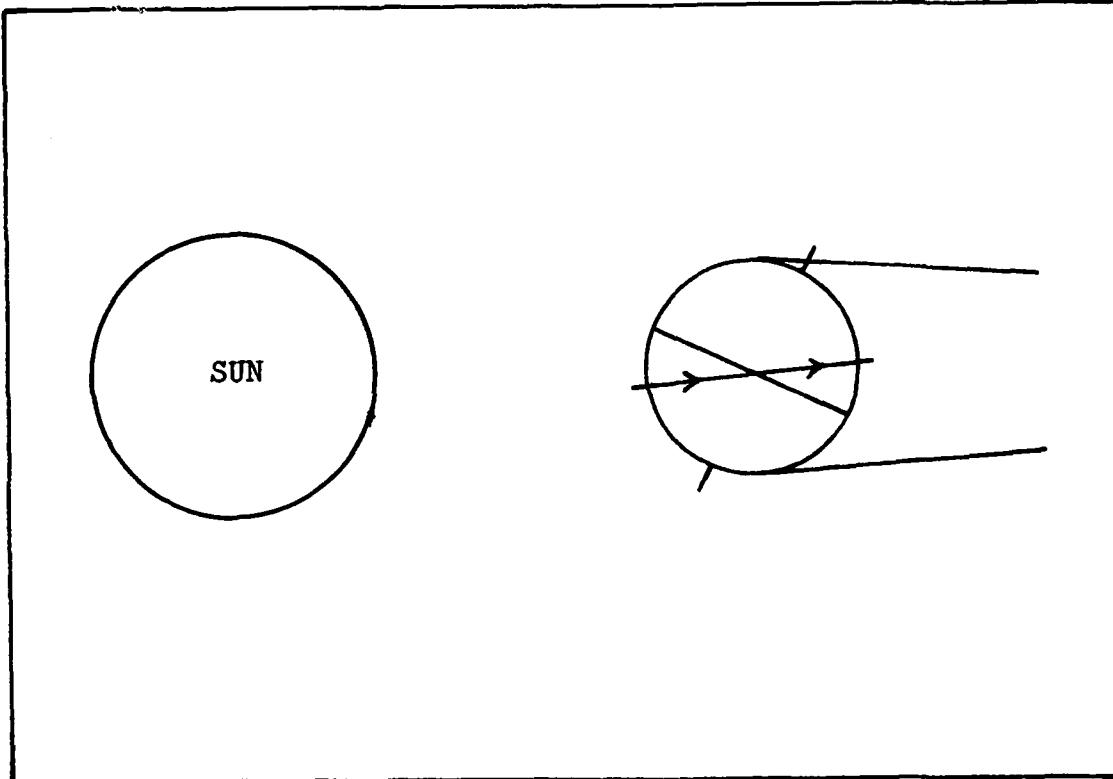

Fig 16. Case III Initial Conditions

For this transfer,  $T$  was only 1.17% greater than the case with no shadow. This small amount represents the penalty associated with maintaining  $\Delta e = 0$  during the orbits when the shadow is penetrated. Even the total transfer time including coasting periods is only 40 TU's or 5.62% longer.

### Case III

The initial geometry for this transfer is shown on Figure 16. These conditions would occur with a midnight launch on the first day of winter. This transfer was chosen because it required the spacecraft to penetrate the shadow for many orbits. As expected, this transfer required more fuel and time. There is a 3.76% increase in  $T$ . The total

time experienced a large 24.8% increase, however. Again, this is not surprising, since the spacecraft had many more coasting periods.

#### Multiple Local Minima

As previously discussed, several minima may exist. Using Case II as an example, it was found that at least two local minima did exist. For  $\lambda_a(0) = -.69023$ ,  $T$  and thrusting time were as described previously and shown in Figure 12. For  $\lambda_a(0) = -.73123$ ,  $T$  was only .001 greater. The two profiles were slightly different. In the second profile, semi-major axis changed more rapidly at first causing shadow exit one orbit earlier.

The presence of multiple minima is not really a problem, however. A reasonable step size for  $\lambda_a(0)$  of .01 identified where the minima could be found. Also, it was noted that there is a specific range of  $\lambda_a(0)$  where these minima seem to occur. If  $\lambda_a(0)$  is such that  $i_f$  is reached first, and, if thrust is used after that point to change  $a$  only, then the amount of time needed to reach  $a_f$  is an indication of whether a minimum can exist in a neighborhood of that  $\lambda_a(0)$ . If  $a_f$  cannot be reached within one orbit, then  $\lambda_a(0)$  does not appear to be near a minimum. A plot of  $T$  versus  $\lambda_a(0)$  seems to be steadily decreasing in this region; see Figure 17. The same argument can be made for  $\lambda_a(0)$ 's where  $a_f$  is reached first. If  $i_f$  cannot be reached within one orbit using only thrust

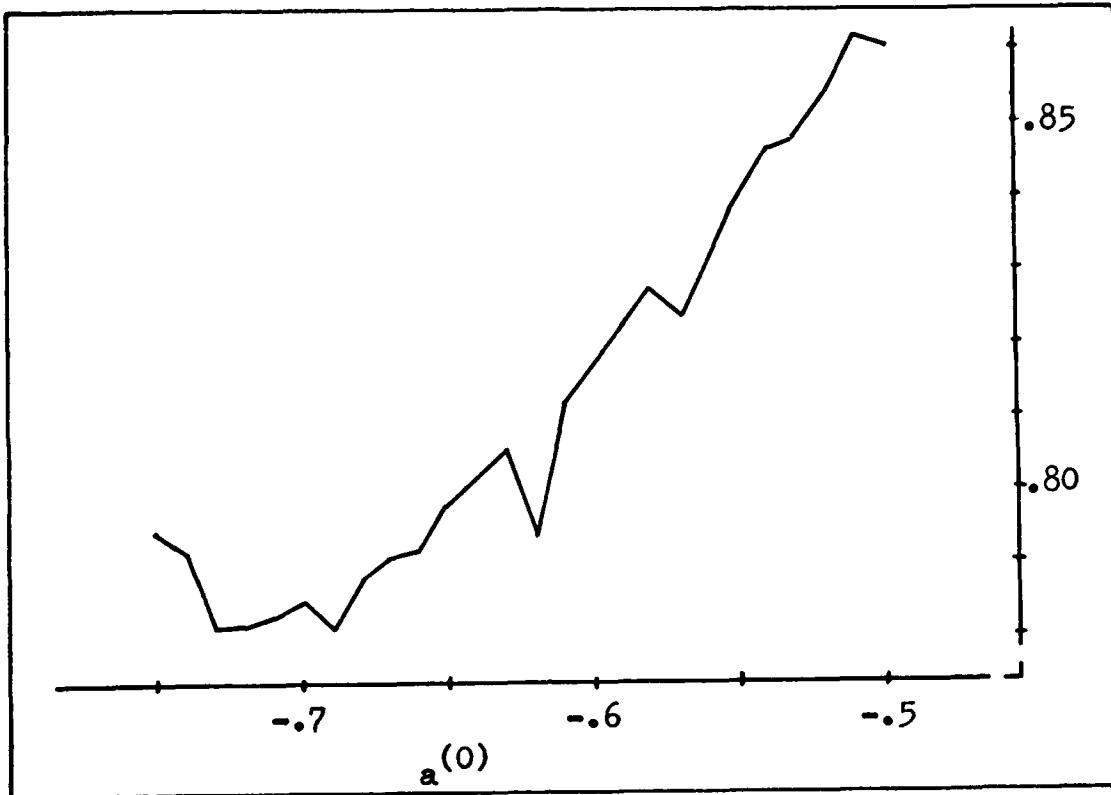

Fig 17.  $T$  versus  $\lambda_a(0)$

normal to the plane, then a minimum does not apparently exist in that region. Again,  $T$  seems to be steadily increasing in this area. In either case, if the other boundary condition can be reached within one orbit, then a minimum is nearby. Also, the new  $\lambda_a(0)$  should be greater if  $i_f$  was reached first and less if  $a_f$  was achieved first. Knowing these characteristics makes it relatively easy to find the minima.

#### General Observations

There are two additional characteristics of these transfers that bear mentioning. Several other initial conditions were used to examine certain characteristics.

Full transfers were not accomplished, but two trends did appear.

The first trend to note is that in no case did the control law direct an inclination change away from  $i_f$ . It was thought that the minimum time solution may require a  $\Delta i$  away from  $i_f$  to reduce shadow time. Apparently, the cost of moving away from the final boundary condition is more than the benefit gained from reducing the shadow.

The other trend that was noticed was that the control,  $u$ , increases until the shadow is less than approximately 2.1 radians. If the shadow is less than that amount,  $u$  decreases. The value at which this occurs is not constant for all the transfers, but it is near 2.1 radians.

It should also be pointed out that these trends were not contradicted in any of these trials.

## V. Conclusions and Recommendations

A minimum time, minimum fuel control law for a vehicle using discontinuous low thrust has been presented. This control is optimal, subject to the constraint that  $\Delta e = 0$ .

If vehicle design prevents continuous thrust application, there is only a small penalty over a design which allows continuous thrust. In particular, an ion rocket powered by solar panels would be competitive with one powered by nuclear power, even if the former could not operate in shadow. The reduction in weight and complexity by eliminating a nuclear power source may more than offset the weight of a small amount of additional fuel.

This solution assumed a spherical earth, as well as constant  $\alpha_0$  and  $\delta_0$ . The oblateness of the earth would cause the line of nodes to regress. Additionally, the actual changes in  $\alpha_0$  and  $\delta_0$  will affect the size of the shadow. These two effects combine to make the length of the transfer highly dependent on the launch time and inclination. The proper selection of when to launch into which initial parking orbit can minimize the effect of shadow penetration.

This solution also assumed low thrust. If thrust is too great, this control law is invalid because  $\Delta a$  and  $\Delta i$  would not be small on each orbit.

A recommendation to further this study would be to find an optimum launch time to perform a given transfer. Another continuation would be to find the optimum control law without requiring  $\Delta e = 0$ .

VITA

John Robert Cass was born on 23 December, 1949 in San Benito, Texas. He graduated from Winston Churchill High School, San Antonio, Texas in 1967. He attended the Air Force Academy and graduated with a degree in Astronautical Engineering. He received a commission into the United States Air Force in June 1975. Pilot training was completed at Webb AFB, Texas where he received his wings in 1976. He became a T-38 instructor pilot at Vance AFB, Oklahoma until March 1980. He then served as a C-5 pilot in the 75th Military Airlift Squadron at Travis AFB, California before entering the School of Engineering at the Air Force Institute of Technology, Wright Patterson AFB, Ohio in June 1982.

SECURITY CLASSIFICATION OF THIS PAGE

↓ This paper examines the use of discontinuous low thrust for orbital transfers between two non-coplanar, circular orbits. The vehicle is assumed to be a solar-powered, ion rocket that cannot operate when it is within the earth's shadow. Two timescales are used to derive a minimum fuel trajectory. The fast timescale solution maximizes a change in inclination when given a change in semi-major axis for a single orbit. The slow timescale solution combines fast timescale results to obtain the minimum fuel trajectory. Results are presented for three specific transfers requiring varying amounts of shadow penetration. It is shown that the fuel penalty caused by discontinuous thrust is small. However, there can be a moderate increase in total trip time if the time within the shadow is large.
